## FRESHWATER ALG $\mathbb{E}$ OF THE LISMORE DISTRICT: WITH AN APPENDIX ON THE ALGAL FUNGI AND SCHIZOMYCETES.

By G. I. Playfair, Science Researcii Scholar of the University of Sydney in Hydrobiology and Plankton.
(Plates xli.-xlvi.; and 11 figures in the text.)
In a previous paper, ${ }^{*}$ I gave some account of the freshwater alge and algal fungi of the Richmond River at Lismore. The following pages are concerned with forms found on land. $\dagger$ The majority of the latter were collected, during 1914, from lagoons, swamps, rainwater-pools, and roadside-ditches almost entirely within the boundaries of the city of Lismore. The following Table shows the general character and composition of the algaflora of these swamp-waters compared with that of the River.

| Algæ. | Land. | River. | Additional. | Total. |
| :---: | :---: | :---: | :---: | :---: |
| Phseophy cex .......... | 7 | - | 7 | 7 |
| Chlorophycee....... ... | 82 | 57 | 62 | 119 |
| Desmidiacere ......... | 116 | 57 | 99 | 156 |
| Heterokontæ ......... | 2 | -- | 2 | 2 |
| Bacillarieæ............. | 36 | 134 | 14 | 148 |
| Myxophyce:e . ........ | 30 | 38 | 11 | 49 |
|  | 273 | 286 | 195 | 481 |
| Algal Fungi. <br> Chytridiacere | 12 | 6 | 9 | 15 |
| Schizomycetes ........ | 13 | 13 | 3 | 16 |
|  | 308 | 305 | 207 | 512 |

The first column gives the total number of forms observed on land, the second the total from the river (l.c., p.95). Records

[^0]for the district additional to those from the river occupy the third column, and the fourth shows the totality of the forms recorded from the Lismore district. As the latter, for the purposes of this paper at any rate, is all included within a circle two miles in diameter, I think the grand total of 512 may be considered indicative of a very rich area.

Samples.-Nos.176-178, 186-188, 190-193, 195-197, 201, 225, are out of weeds in the river or creeks; 185, 240, swamp on Woodlawn Road; 223, 241, 260, 261, lagoon behind Foley's; 227, ditto at Woodburn; 236, 237, 259, ditto near North Lismore Station; 238, 254, 255, 258, ditto near Cemetery, Goolmangar Road; 233, rainwater pools, Woodlawn Road; 242, 243, ditto near Girard's Hill; 244, 246, 251, ditto near Drill Hall; 245, 247, ditto in Conway Street; 248, 249, ditto on Wyrallah Road; 250 , ditto near Convent; 253 , ditto North Lismore. The follow ${ }^{-}$ ing are in the form of mucous strata: 202, river-bank, Coraki; 199, 208, open drain, Keen Street; 206, on curbstone at Nisbet's; 207, open drain near Cathedral; 211, 221, 228, 229, 232, ditto in Carrington Street; 226, ditto in Terania Street; 231, 252, ditto near Presbyterian Church; 210, on zinc-footwasher; 205, 209, horse-trough near Post Office; 212, ditch in Conway Street; 213, 230, ditch in Magellan Street; 256, 257, on rocks, New Cut.*

Chlorophycece. There is the same extraordinary dearth of Protococcacere in the swamps and lagoons of the district as in the river-system, in striking contrast to their prevalence round Sydney, where I have obtained them in such quantities as to make the water, in which they were, quite gelatinous. All the usual genera, however, were observed. On the other hand, the Volvocacere are well represented and plentiful (in the rainy season especially), as was the case also with the green flagellate infusoria. Out of a total of 82 forms of Chlorophycece noted, no less than 31 (or nearly $40 \%$ ) belong to the Volvocacere, representing nine genera, viz., Carteria, Chlamydomonas, Phacotus, Pteromonas, Gonium, Pandorina, Eudorina, Volvulina gen.nov., and Volvox. Indeed, the predominance of the green flagellates (both

[^1]algal and infusorial) is characteristic of the district, just as the predominance of the diatoms is of the river. Not a sign of the Phytheliece was seen, though repeated gatherings were made from shallow meres on grassland, which are said to be their favourite haunt. Out of a total of 119 forms of Chlorophycere from swamp and river, only 20 were common to both.

Phceophycece.-The absence of Dinobryon, which was remarked in the river, is noticeable also in the swamp-waters. Only two small fragments were observed. Synura was plentiful. Chloromonas, as usual, frequently present in gatherings but always sparsely discributed. The most interesting item in this Class, however, is the discovery* of a large and handsome flagellate resembling Volvox, but corresponding in structure and characteristics more to my new genus Volvulina in the Volvocacea. To receive this form, it has been necessary to propose a new genus of Syugeneticce, to which I have given the name T'essella.

Desmidiacere.-The desmids attain to the respectable total of 156 for the whole district, including the river; but, in no case, were they found in abundance. I am inclined to attribute this, as also the deficiency of Protococcacere, to the character of the soil, which is a fine loam, very deep, so that water does not lie very easily, and the surface dries very rapidly. Most promising lagoons here yield next to nothing in the way of desmids, while in the Parramatta district and the coastal district of Sydney (Botany, Coogee, Centennial Park) where the soil is clay, or sand with rock underlying at no great depth, little patches of swampy ground, where water lies regularly after rain, will often yield a certain set of desmids in profusion. It is noteworthy that the desmids of the river are almost entirely different from those found on land. Out of 156 forms, only 17 are common to both, and of these 11 are varieties of C'losterium, a genus whose forms seem to flourish equally well in almost any habitat. The 116 forms noted on land represent 13 genera, but only the very commonest. Netrium, ''etmemorus, Sphcerozosma, Phymatodocis, and Triploceras even were not observed. The absence of the last is re-

[^2]markable, as its forms are frequent round Sydney, and Phymatodosis also is found there locally. As in the river, forms of Closterium (29) and Cosmarium (30) form the bulk of the desmidflora, accounting for exactly half, Euastrum and Staurastrum (11 each), Penium and Xautlidium (7 each), Docidium (6), Micrasterias (5), and Gonatozygon (4) make up the bulk of the remainder.

Bacillariece.-It is strange that the swamp-waters should be so poor in diatoms (plentiful enough round Sydney), especially considering that they bulk so largely in the river. Only 36 forms were met with, representing 13 genera, as against 134 in the river, with 27 genera. Only 22 were common to both, viż, Pinnularia (5), Nitzschia (4), Vanhenrckia (3), Gomphonema (3), Cocconema (2), Javicula, Achuanthes, Synedra, Stenopterobia, and Hantzschicu ( 1 each). It is curious and interesting to note that, out of 21 forms of Naviculu (including Diadesmis), only one, Nav. mutica var. Güppertiana, is common to both land and river.

Myxophycere. - The township of Lismore is rich in these, chiefly forms of Oscillatoriacere. In roadside-ditches and concrete water-tables, and wherever there is a regular dribble of water, mucilaginous strata are sure to form. Enmeshed in them may be found certain diatoms in some quantity, sometimes, indeed, in such abundance as to give to the stratum their own distinctive yellow-brown colour. In general also, while consisting principally of one species, they contain others in lesser quantities, e.g.:
(26).L. Lismorensis, L. K'ützingii var. distincta, O. formosa, O. splendida var. amylaceu, and var. limnetica, Ph. tenue, Spirulina laxissima.

Nitzschia palea var. debilis, N. vermicularis var. vialis, and var. minuta.

Nav. lanceolata, with var. curta and var. arenaria.
(27).Spirulina major, O. formosa, O. Corakiana, O. acuminata, O. splendida var. amylacea, and var. limnetic., [0.] amphibia (Spirillum filament), Spirillum volutans, Spirulina C'orakiuna, Nitzschia obtusa var. scalpelliformis.
(30).Phorm. corium, Ph. tenue, Plect. nostocorum, L. Lismorensis, and var. nigra, Calothrix Braunii, Nitzschia subtilis, and var. palacea, Syn. ulna,

The first-named, in each case, is the prevailing form.
New forms.-In the following notes, two new genera have been proposed, and 17 species, 33 variations, and 8 forms ( 58 in all) have been described as previously unrecorded. These are allocated as follows, Algæ(53):-Phceophycere 5, Chlorophycece 20 (all but one are Volvocacere), Desmidiacece 18, Bacillariece 4, Myxophycere 6. Algal fungi (5):-Chytridiacere 4, Schizomycetes 1 .

## PH ÆOPHYCE Æ.

Genus Sine ra Ehr.
Synura uvella Ehr. (Pl. xlv., f.1, 2.)
Cell. long. 22, lat. $11 \mu$.
Lismore (242); W yrallah.
Lemmermann, Plankt. Schwed. Gewass., p.119, describes the test of Synura uvella Ehr., as membranous ("membran hautartig") which implies that it is smooth. I have restricted the name, therefore, to such specimens.

> Synura granulosa, n.sp. (Pl. xlv., f.3.)

Testre ovato-claviformes, fronte rotundatæ, a tergo attenuatæ; granulis minutis sparsis ornatis.

Cœn. diam. 55-100; cell. long. 35, lat. $10 \mu$.
Lismore (223, 241, 249, 260, 261).
Synura granulosa is the common Synura of this country. The test shows as a granulate hyaline border even in living specimens. In all our forms of Synura, setæ are very rarely present. G. S. West, Br. Frw. Alg., p.46, gives the colour of the chromatophores as brownish-green in European specimens of Synura, but here they are yellow-brown.

Var. pusilla, n.var.
Testæ subglobosæ, minute granulatæ. Ccenobia parva, cellulis paucis.

Lismore (260).

This is a young form of the species, the cœnobia being smaller, the cells few and suborbicular. The cœnobia are formed, of course, by the self-division of (originally) a single individual. It is not uncommon to find specimens consisting merely of two cells tail to tail. In such, the subglobose shape is very distinct; as the cœnobia become larger, the cells become more fusiform.

Synura australiensis, n.sp. (Pl. xlv., f.4, 5.)
Testæ fusiformes, fronte truncatæ, membrana tenui glabra.
Cœn. diam. 70-140; cell. long. 45, lat. 5-8, ap. $2 \frac{1}{2}-3 \mu$.
Lismore (260, 261).
A very beautiful and distinct species; some magnificent clusters were noted. The membrane is thin and quite smooth; the test does not show as a hyaline border. No marginal setæ, apparently two contractile vesicles on each side below the centre.

## Genus Din obryon thr.

Dinobryon seitularia Ehr.
Dinobryon is very rare in this district; after over two years' thorough search, I have noted two isolated sprays.

Wyrallah, lagoon.
Var. CONICUM, nom.nov.
Testæ hyalinæ, conicæ, inferne acuminatre, lateribus leviter arcuatis, ore non everso.

Lismore (260).
Syn., Dinobryon sertularia Ehr., forma, Plankt. Syd. Water, p.515, Pl.57, f.5.
'Tessella, gen.nov.
Character idem ac speciei.
Tessella volvocina, n.sp. (Pl. xlv., f.6, 7.)
Cœnobium molle, mucosum, sphæricum, cavum; e strata unica cellularum exstructum, integumento mucoso, minute granuloso, investitum. Cellulæ (ut videtur) pulviniformes, a vertice visæ inæqualiter circulatæ vel polygoniæ, pæne contingentes; a latere depressæ, flagellis binis præditæ. Chloroplastides binæ(?), aut singulæ genuflexæ(?), luteo-fuscescentes vel luteo-virides, granulis
magnis (pyrenoidibus?) aliquot plerumque 3 , vesiculis contractilibus aliquot(3-5 ?), instructæ. Stigma rubrum non vidi.

Cœn. diam. 30-170; integ. crass. 4; cell. diam. $10 \mu$.
Lismore (260).
This interesting Volvox-like Hagellate, all the more interesting because it does not seem to belong to the green algæ, is found in lagoons. I first noted it many years ago, at Pott's Hill, near Auburn, but it is distinctly rare. The cœnobium is hollow and flaccid; even when revolving freely, it cannot retain the spherical shape, but gets dented in here and there. It is formed of a single layer of large, cushion-shaped cells, irregularly circular or polygonal when seen from above, and nearly touching. The chloroplasts are yellow-brown or yellow-green in colour, as in Synura, in company with which it is often found. The protoplasmic contents of the cells are homogeneous and refractive, and I have never been able to make certain of the shape of the chloroplasts. From above, the cell shows a central clear strip with a parietal chloroplast, or fold of a chloroplast, on each side. There are several large granules present, acting, perhaps, as pyrenoids. A number of rather large pulsating vesicles were observed in each cell; the cystole and diastole are both very slow and gradual. Two flagella noted, but no stigma. I have arranged this form near Syuura on account of the colour of the chloroplasts.

## CHLOROPHYCEÆ.

## Fam. ZYGNEMACEE.

Gelus $\mathrm{Z}_{\mathrm{y}} \mathrm{g} \mathrm{nema}$ Ag.
Zygnema pectinatum (Vauch.) Ag., forma.
Fil. diam. 26; cell. alt. $60 \mu$.
Lismore (240).
A form in which the outer sheathing membrane has been ruptured, and the cells are merely adherent by the apices. It seems to throw some light upon the formation of Debarya. I have noted the same form from Kogarah (diam. 24, cell. alt. 50$70 \mu)$. The broken sheath may be seen at the angle of one of the cells (Pl. xlii., f.l).

## Genus Spirogyra Link.

## Spirogyra crassa Kütz.

Cell. veg. diam. 160-180, alt. plerumque 120-190, interdum 50 ; membr. crass. $2 \mu$.

Lismore (249).
Six, narrow, smooth chloroplasts making one turn each. Pyrenoids very numerous, large for the size of the chloroplast, taking up the full breadth or a little more.

Spirogyra Grevilleana var. australis, n.var. (Pl. xlii., f.2.)
Forma zygosporis ellipticis acuminatis, præ longitudine valde latioribus.

Cell. veg. diam 30, alt. 160-230. Zygo. long. 75, lat. $50 \mu$.
Lismore (248).
Cf. Sp. Grevilleana (Hass.) Kütz. in Petit, Spir. d. Paris, p. 10 Pl. ii., f.l-6, (fig. 6 has pointed zygospores); also Borge, Zygnemales, in Pascher, Sussw. Fl. Deutschl., p.17, f.4. The chloroplasts of the vegetative cells are sometimes single, making 5 to 7 turns, sometimes double, making only $2 \frac{1}{2}$ turns, the edges scalloped, and pyrenoids very small. Ends of cell reflexed. The zygospores are elliptic with pointed ends, not oval, and much broader in proportion than in the type. Sporangial cells very much swollen.

## DESMIDIACE F.

Genus Gonatozygon DeBary. Gonatozygon monotenium DeBy.
Long. 101-144, lat. centr. 11-12, ap. $12 \mu$.
Lismore (223, 254, 260).
Var. tenue, n.var. (Pl. xli., f 1.)
Cellulæ quam forma typica angus̀tiores; apicibus haud expansis in cellulis liberis arcuatis nec planis.

Long. 80-150, lat. centr. 8, ap. $8 \mu$.
Lismore (223).
The dimensions agree with the lowest of those given by W. \& G. S. West, Monog. i., p.30, but the shape of the cells is unusual, the diameter the same from centre to apices, the extreme ends
in free cells not flat and incrassate but strongly arcuate and thin-walled as in loose cells of Mougeotia. This is most unusual in Gonatozygon, and is probably the result of rapidly repeated division.

> Gonatozygon Brebissonii var. minutum W. \& G. S. West. (Pl. xli., f.2.)

Long. 65, lat. 4, ap. $3 \mu$.
Lismore (261).
Cf. W. \& G. S. West, Br. Desm., i., p.33, Pl. i., f.15. The type also noted. Pl. i., f. 16 of the Monograph should be placed under var. Kjellmanni(Wille) Rac.; (Gon. Kjellmanni Wille, l.c.).

## Genus Penium Bréb.

Pen. margaritaceum var. pulverulentum, n.var. (Pl. xli., f.3.)
Forma puncta-granulis minutissimis sparsis nec in seriebus ordinatis ornata.

Long. 147, lat. 21 , isth. 20 , subap. $18 \mu$.
Lismore (185).
The type, with small but distinct granules in longitudinal series, is very rare in this country; I have seen it only once. Var. irregularius W. \& G. S. West, Alg. fr. Orkneys and Shetlands, p.14, Pl.i., f. 23 (by clerical error, var. irregulare in G. S. West, Alg. Yan Yean Res., p. 53) has larger granules irregularly disposed. In this form, on the other hand, the granules are minute, indeed hardly noticeable at the edges. Membrane very faintly rufescent, almost hyaline.

Var. indivisum, n.var. (Pl. xli., f.4, 5.)
Forma haud constricta, isthmo nullo, polos versus leviter attenuata; lateribus planis parallelis, vel levissime arcuatis, apicibus rotundatis subtruncatis; membrana puncta-granulis minutissimis sparsis ornata, dilutissime luteola vel hyalina; chloroplastidibus in medio interruptis.

Long. 74, lat. 20 , ap. $17 \mu$.
Lismore (185). Cum priori.
This form is the result of repeated self-division. A specimen is figured with one end expanded.

Pen. cucurbitinum var. subpolymorphum f. crassior, n.f.
Forma paullo major quam forma typica, præ longitudine paullo latior; apicibus rotundatis nec subtruncatis.

Long. 25, lat. $50 \mu$.
Lismore (185).
A form somewhat larger and slightly broader than Nordstedt's type, Frw. Alg. N.Z., p.71, Pl.7, f.20. For a length of $95 \mu$, his figure gives a breadth of $42 \frac{1}{2} \mu$, which agrees with specimens gathered by Lütkemüller in Austria (Desm. d. Attersees, p.8). The latter gives long. 96-100, lat. 40-42, lat. constr. $36 \mu$. In the very slight constriction, however, our form resembles the type. (Pl. xli., f.6.)

## Genus Closterium Nitzsch.

Closterium Spetsbergense var. palustre, n.var. (Pl. xli., f.7.)
Forma gracilior, juxta polos acutior; latere dorsali plano pæne usque ad polos, quam levissime recurvato in extremis; latere ventrali arcuato polos versus pæne recto; apicibus truncatis incrassatis; membrana hyalina, glabra, punctis nullis nee striis.

Long. 275, lat. 34, ap. 7-8 $\mu$.
Lismore (185).
Cf. Cl. Spetsbergense Borge, Süssw. Alg. Spets., p.8, fig.5, of which the author remarks that a very closely connected form is Cl. lanceolatum $\beta$ coloratum (Klebs) Playf., Some Syd. Desm., p. 604 Pl.xi., f.1. From the figures in W. \& G. S. West, Brit. Desm., i., however, it is evident that the latter is not Cl. lunula $\beta$ coloratum Klebs, which it was supposed to represent. It might stand, therefore, as $C l$. Spetzbergense var. australe mihi. For the type, Borge gives: Crass. cell. $40-46 \mu$, crass. apic. $6-7 \mu$, crassitudine $5-6 \cdot 5$-plo longius. The Sydney specimen figured, l.c., measured $270 \times 45$, ap. $7-8 \mu$. Cf. Cl. lanceolatum Kütz.(?) in Cleve, Sveriges Söttv. Alg., T. iv, f̂.7.

Closterium acerosum var. Casinoense Playf.
Long. 440, lat. $40 \mu$. Membrana dilute luteola, obscure striata.
Lismore (248).
Cf. Biol. Richm. River, these Proceedings, 1914, p.101, Pl. iii., f.5.

## Closterium gracile Bréb.

Long. 166, lat. 6, ap. $2 \mu$.
Lismore (254, 260); Wyrallah.
The breadth of our specimens of Cl. gracile is nearly always $6 \mu$, occasionally $7 \mu$. It is evident from Brébisson's note (Liste, p.155) that the generally accepted type of this species is not what its author had in view. He says "peu attenué aux sommets qui sont légèrement courbés et obtus." The bluntended form, therefore, is, strictly speaking, Brébisson's type, and this accounts for the curious shape of the apices in his figures. This point, however, is not mentioned in the Latin description.

Var. elongatum W. \& G. S. West.
Long. 300, lat.7, ap. $2 \mu$.
Lismore (223).
Cf. Monog., i., p.168; the authors give lat. 3-4 $\mu$, but, in this country, its breadth ranges from 5 to $\delta \mu$.

Var. bicurvatum (Delp.) mihi.
Forma Cl. gracilis sepissime bi-undulata, apicibus obtusis truncatis.

Long. 265-400, lat.6, ap. $3 \mu$.
Lismore (260). Cum f. typica.
I first obtained this form many years ago in profusion, from weeds out of a tank in the Botanic Gardens. There is no doubt of its being Cl. bicurvatum Delp., Desm. Subalp., ii., p.209, T.18, f.37-39. The hollow back, which makes it bi-undulate, and the blunt ends sufficiently characterise it. It is also certainly a form of Cl. gracile, cf. Borge, Feuerland u. Isla Desolacion, p.30, fig.6. Cl. toxon West, in Monog. i., p.160, Pl.20, f.13, 14, is really a forma crassior of this variation.

Var. substrigosum (Rac.) mihi. (Pl. xli., f.8.)
Forma Cl. gracilis apicibus subrostratis, extremis acutis.
Long. 114-250, lat. 5-6, rarius $8 \mu$, ap. $1 \frac{1}{2}-2 \mu$.
Lismore (260).
Syn., Cl. macilentum $\beta$ substrigosum Rac., Desm. Ciast., p.9, T.1, f.38; Cl. substrigosum W. \& G. S. West, Alg. fr. Burmah, p.192, Pl. xiii., f.19. In this form, the sides do not converge
evenly to the apices, but, when a short distance from the tip, the concave side becomes more or less parallel to the other, making the end subrostrate. Not at all uncommon round Sydney, generally mixed with the type. Quite certainly a form of $C l$. gracile.

Closterium pronum Bréb. (Pl. xli., f.9.)
Long. 300, lat. 8-10, ap. $2 \mu$. Membrana luteola, striis nullis. Kyogle.
Brébisson, Liste, Pl. ii., f.42. Not Cl. pronum W. \& G. S. West, Monog., i., Pl.23, f.1-3( = Cl. acutum forma major), nor Cl. pronum Klebs, Desm. Ostpreuss., p.19, T. ii., f.12a (=Cl. linea Perty, f. major. The extremities of the cell, it should be noted, are filiform, shorter, however, than the part of the semicell in which the chloroplast lies. These details agree exactly with Brébisson's note (Liste, p.157). Moreover, he unites Cl . pronum with $C l$. setaceum, $C l$. Kützingii and others, in a group characterised as "Corpuscules fusiformes terminés par un long bec sans endochrome (Stauroceras Kütz.)." Cl. pronum is quite unlike the forms of Cl . acutum with which Klebs classes it; the membrane also is of quite a different character.

Closteriux Kutzingil var. capense Nord.
Long. 285, lat. $15 \mu$.
Lismore, Kyogle, cum priori.
Desm. Lugduno-Batavi, p.1, f.1, including C'l. Kützingii Bréb., ibid A small form having, in length, the same range as $C l$. pronum, in company with which it is nearly always found here. It is more inflated, however, in the centre, the breadth varying generally from $14-16 \mu$, with about the same relative proportions of body and rostrum as in C'l. pronum. Biologically, indeed, it is a form of that species. The membrane is usually faintly yellowish and clear, occasionally distinctly striate.

> Cl. preflongum Bréb. (Pl. xli., f.10.)

Long. $565-\mathrm{i} 70$, lat. $14-20$, ap. $4-5$, subap. $6 \mu$.
Lismore (223, 225, 254, 259, 260).
This species is characterised by W. \& G. S. West, Monog., i., p. 165 , as one of the rarest species of the genus. It is not un-
common, however, at Lismore, especially in shallow meres and pools on grassland, and is not infrequent round Sydney. Australian forms differ from the European in being less regularly arcuate, much straighter in the back, and suddenly bent in, about one-third of the distance from the ends. Also particularly in the tip, which is only the very slightest bit recurved (not at all as in Monog. i., Pl.21, f.1-3). The membrane is nearly always pale yellow or pale buff, and not striate.

Forma brevior West.
Long. 162-345, lat. 18, ap. $4 \mu$. Membrana dilute luteola.
Lismore (223, 236, 254).
Cf. Cl. praelongum var. strigosum (Bréb.)(?), these Proceedings, 1908, p.605, Pl. xi., f.3; which gives a good idea of Australian forms of Cl . pralongum, but the extreme tip should be very slightly recurved. I doubt very much if the form figured, l.c., is identical with Cl. strigosum Bréb.; it is a specimen of Cl . proelongum f. brevior West, in which the tips are quite straight, not recurved at all. The dimensions may be taken as including f. brevior, as my description says "apicibus . . . . nonnunquam levissime reflexis." There is no real difference either between f. brevior and Cl. tumidum Johnson; they are only degrees in reduction; the recorded length of Cl . tumidum overlaps that of f. brevior, and the length of the latter runs right up to the type. They all three have the same range of breadth; Cl. proelongum lat. 14-24, f. brevior 16-24, Cl. tumidum $18-24 \mu$ are my records.

## Closterium tumidum Johnson.

Long. 150-180, lat. 23-24, ap. 5-6 $\mu$. Membrana dilute luteola. Lismore (236). Cum priori.
Cl. tumidum Johnson (syn., Cl. cornu in Wille, Fersk. Nov. Semlja, T. xiv., f.80, 81) is biologically a form of Cl. proelongum very much reduced by repeated self-division. I find it always in company with forms of that species. The membrane and apices also are of the same character in both. Repeated division immensely reduces the length of the cell without alteration of the breadth.

Genus Cosmarium Corda.
Cos. rectangulare var. nodulatum f. minor Playf.
Long. 40, lat. 31, ap. 12 , isth. $10 \mu$. Noduli apicales abfuerunt. Lismore (185).
Cf. Polym. and Life-hist., p.476, Pl.iii.,f.5. The apical nodules are sometimes wanting in these forms of Cos. rectanyulare. (Pl. xli., f.11a).
Cos. rectangulare var. Boldtil f. minor, n.f. (Pl. xli., f.11b.)
Forma minor, angulis basalibus magis rotundatis; lateribus e basi levissime divergentibus.

Long. semic. 12, lat. 22, ap. 10, isth. $10 \mu$.
Lismore (185).
Found only as companion-semicell to one of the previous form (nodules present, however). Cos. rectangulare forma, Boldt, Desm. Grönl., 'T. i., f.18, to which I gave the name var. Boldtii in Some syd. Desm., p.613, measured 43-44×34-36 $\mu$. This form, though only about one-half the size, is almost exactly like Boldt's figure.

Cos. rectangulare var. biretum, n.var. (Pl. xli., f.12.)
Forma parva; semicellulæ inæqualiter hexagonæ; e basi plana lateribus levissime divergentibus (paullo magis quam in var. Boldtii f. minore) ad apices rapide convergentibus; apicibus truncatis paullulo productis; angulis lateralibus latissime-rotundatis, basalibus obtusis; isthmo angusto. Membrana levis infra apicibus papillis singulis interdum ornata.

Long. 25, lat. 22, basis 19, ap. 8-9, isth. $6 \mu$.
Lismore (185).
Forma rectilinearis, n.f. (Pl. xli., f.13).
Forma lateribus rectis, apicibus non productis, angulis lateralibus obtusis nec rotundatis.

Long. 27, lat. 22, basis 19, ap. 8, isth. $6 \mu$.
Lismore (185).
Forma angustior, n.f. (Pl. xli., f.14.)
Forma angustior, parte superiore laterum retusa.
Long. 26, lat. 20, basis 16, ap. 8, isth. $6 \mu$.
Lismore (185).
Something like Cos. (Eu.) leiodermum Gay, Conj., p.58, Pl. i., f.16, which itself is a form of Cos. rectangulare Grun. Differs
from Cos. rect var. africanum W. \& G. S. West, A]g. Centr. Afr., p.377, Pl.361, f.14, in having the upper part ot the sides retuse. Var. biretum and its forms are all closely connected with var. Boldtii. f. minor, supra, indeed are merely modifications of it; and their association, in the same gathering with the mixed form of var. nodulatum and var. Boldtii f. minor, shows quite plainly how smaller forms, with new characteristics, are produced from a very different type by repeated self-division.
Cos. Rect. var. quadrigeminatum f. latior, n.f. (Pl. xli., f.15.)
Forma paullo minor. Semicellulæ quam f. typica paullo latiores; apicibus nodulis 4 (fronte cernendis 2) aut infra marginem, aut protrusis, instructis; a latere globosæ apicibus nodulis 2 (cernendis) ornatæ.

Long. 36, lat. 28, basis 23, ap. 12, isth. $9 \mu$.
Lismore (185).
Syn., Cos. rcct. var. Cambrense (Turn.) W. \& G. S. West, forma, Polyın. and Life-hist., p.476. This form falls better here than under var. Cambrense, as the latter is a form with square semicells.

Cos. Rect. var. angustius f. minor, n.f. (Pl. xli., f.16.)
Forma dimidio minor. Semicellulæ inæqualiter hexagonæ, parte superiore arcuata angulata; angulis lateribus pæne centralibus; lateribus haud retusis; apicibus truncatis angustis. Vertice visæ ellipticæ polis acuminatis.

Long. 16, lat. 12, basis 10, ap.4, isth. $2 \mu$.
Lismore (185).
Cf. Nordstedt, N.Z., Pl. vi., f.15, 16. The figures of Cos. pseudoprotuberans $\beta$ angustius Nord., contain two distinct types. Of these, the lower semicell of f .15 and the upper semicell of f .16 are identical with Cos. rect. var. Finmarkice Playf., Polym. and Life-hist., p.478, Pl. xiii., f.13. The other semicells, with angular apices, I have arranged as Cos. rect. var. angustius (Nord.), l.c., p.477.* The latter is certainly a form of Cos. rectangulare. The

[^3]form under consideration somewhat resembles Cos. sexangulare f. minima Nord. It is of the same size, but the apices are narrower, and the sides not at all retuse; the lateral angles also opposite the centre of the semicell, higher rather than lower. Cf. Nordstedt, N.Z., p.60, Pl. vii., f.26, 27; W. \& G. S. West, Monog. iii., p.82, Pl.72, f.4, 5. It should be remembered that Cos. sexangulare Lund., and Cos. sulcatum Nord., are themselves, biologically, forms of Cos. rectangulare Grun., cf. Polym. and Life-hist, p.481-2, Pl. xiii, f.20-22. All the above forms, with Cos. rect. var. cyclopeum Playf. $(30 \times 24$, basis 16 , isth. $5 \mu$ )., l.c., Pl. xiii., f.7, were found together in the same gathering; compare my remarks, l.c., p. 475.
Cos. pseudoprotuberans var. australe, n.var. (Pl. xli., f.17.)
Forma major validor. Semicellulæ papillis binis infra apices a fronte non cernendis; a vertice ellipticæ apicibus acuminatis, utrinque in medio papillis binis instructæ.

Long. 50 , lat. 42 , basis c. 28 , isth. $9 \mu$.
Lismore (185).
With the type, $34 \times 28$, isth. $6 \mu$. This large form is not at all uncommon round Sydney, in shallow waters where Xan. hastiferum is to be found. It is practically a spineless form of the latter. Cos. pseudoprotuberans forma, Borge, A ustral. Süssw. Alg., p.23, T.3, f.39, is certainly a form of Cos. rectanyulare, probably near to, if not identical with, var. australe, Playf., Polym. and Life-hist., p.480, Pl. xiii., f.14, 15.

Cos. moniliforme var. subquadratum, n.var. (Pl. xli.,f.I8.)
Semicellulæ subquadratæ ubique rotundatæ, apicibus paullo deplanatis; a vertice visæ, orbiculatæ. Membrana glabra.

Long. 30, lat. 18, isth. $3 \mu$.
Lismore (185).
One semicell was very slightly produced and angulate at each side, a little above the centre. This indicates a connection with Cos. pseudoprotuberans. Var. subquadratum is intermediate between Cos. moniliforme and Jacobsen's form (Cos. Jacobsenii Roy). It shows that Nordstedt was right in making the one a f. elliptica of the other (Norges Desm., p.22). W. \& G. S. West,

Monog. ii., p.171, Pl.61, f.26, have just as correctly arranged Cos. Jacobsenii as a variation of Cos. contractum, as the latter is the base of the whole series. It is an instance of the difficulties that attend the arranging of a lot of closely connected, polymorphic forms, not one of which can be definitely particularised as the direct outgrowth of any other; on a basis, too, partly of outline, and partly of a biological connection which cannot be evaded.

Cos. obsoletum var. Sitvense f. dentata, nom.nov. (Pl.xlii.,f.3.)
Long. 54-56, lat. 58-60, isth. 28, crass. $34 \mu$.
Lismore (180).
Cf. Cos. obsoletum var. Sitvense Gutw., in W. \& G. S. West, Monog. ii., Pl.56, f.4. Neither of Gutwinski's figures, however, (Alg. in Java coll., T.38, f.39, 40) has a tooth at the basal angle, nor is it mentioned in his description, l.c., p.594. The authors of the Monograph are in error, also, in considering the basal angles to be incrassate, with a central pore. The hyaline tip is formed by an extension of the fine outer primordial membrane of the cell, and the supposed pore is a true conical tooth. Cf. Nordstedt, De Alg. Lugd.-Bat., p.7, fig.9. In Gutwinski's figures, this outer membrane is shown separated from the cellwall all round. The sloughing of this membrane is well known in Doc. trabecula. I have observed it also in Cos. glyptodermum W. \& G. S. West, in which case the marks of the large depressions were plainly visible on it Not only is there a decided tooth at the basal angle in this form, but occasionally from two to four teeth form in a vertical line at the extreme edge, bursting the outer membrane, and giving rise to Cos. auriculatum, which is, therefore, a form of Cos. obsoletum. A mixed form of f. dentata mihi and Cos. auriculatum forma was observed. Cf. Pl. xlii., f.5. There is nothing extraordinary either in Cos. obsoletum having a tooth at the basal angle; it is found just as decidedly in Cos. Smolandicum Lund. Gutwinski's description of var. Sitvense, l.c., p.594, says "membrana granulata"; this is a mistake, as his own figures show. The membrane is covered with very coarse puncta-scrobiculæ.

Cos. auriculatum Reinsch. (Pl. xlii., f.4,5.)
Long. 57 , lat. 57 , isth. 25 , crass. $30 \mu$.
Lismore (185).
As I have not access to Reinsch, Contributions, I have had to depend on Turner, Alg. E. Ind., p.50, Pl. vii., f.35, and Pl. ix., f.8. The latter is said by the author to be verrucose, but, as his figure does not show any verrucæ at the margin, the membrane had probably the coarse puncta-scrobiculæ of Cos. obsoletum var. Sitvense Gutw. Although Cos. auriculatum is certainly a form of $C$. obsoletum, yet, on account of its distinct shape, it is best kept separate. Cos. laticollum Delp., Desm. subalp., ii., p.116, T.8, f.20-23, C. erosum Delp.,l.c., Pl.8, f.24-27, and Cos. suberosum Gutw., Alg. in Java coll., p.592, T.38, f.36, might all be very well arranged as variations of this type.

Cos. venustum var. Borgei, nom.nov. (Pl. xli., f.19.)
Forma lateribus e basi plana ad apices truncatos sensim convergentibus, valde undulatis; lobis lateralibus nullis; lobo apicali rectangulari, lateribus verticalibus parallelis; supra medium granulo instructa.

Long. 30, lat. 22, isth. 4; lob. apic. lat. 12, alt. $6 \mu$.
Lismore (185).
Syn., Cos. venustum, forma, Borge, Nordanerik. Süssw. Alg., p 8, tig. 5 . The latter gives long. 31-321 $\frac{1}{2}$, lat. 19-191 , ap. 13-14 $\frac{1}{2} \mu$ as the dimensions. Cf. Cos. venustum, forma, Borge, Austral. Süssw. Alg., p.23, T.3, f.40, which is somewhat larger, but is a form of this variety. It is the common Australian form.

Cos. Askenasyi var. crateriforme, n.var. (Pl. xlii., f.6.)
Semicellulæ crateriformes adpressæ; sinu lineari extrorsum ampliato; basi plana; angulis basalibus latissime rotundatis, granulis paucis sparsis ornatis; lateribus convexis ad apicem convergentibus; apicibus angustis levissime deplanatis. Inflatione(?) supra isthmum.

Long. 158, lat. $126 \mu$.
Lismore (240).
For the type, see Schmidle, Alg. Sumatra, p.304, T.iv., f.7. This form is very close to the forma in Borge, Austral. Süssw.

Alg., p.21, T.3, f.35, but form more regular, base flatter, semicells more adpressed, apex flattened, fewer granules (spines in his form). Cf. also Bernard, Protococc. et Desm., p.113, f.175, and f. javanica Gutw., Alg. in Java coll., p.596, Pl.38, f.45( $=$ Cos. spec., Möbius, Austral. Süssw. Alg., ii., p.340, T.ii., f.20; long. 110 , lat. 94 , isth. $43 \mu$ ), which is broader in proportion.

Cos. Blyttil var. Lismorense, n.var. (Pl. xlii., f.7.)
Semicellulæ fere rectangulares; apicibus productis, truncatis 4 granulatis; lateribus e basi plana verticalibus, parallelis, 4 granulatis, infra marginem granulis paucis; angulis basalibus superioribusque fere rectis; a vertice visæ, ellipticæ, papillis nullis.

Long. 17, lat. 16, ap. 8, isth. $4 \mu$.
Lismore (185).
The body of the semicell is transversely rectangular, the apex suddenly produced above, with a marked hollow on each side between it and the upper angles, sides of semicell almost vertical, basal and upper angles almost square, just rounded off; sides and apex 4 -granulate, with inner series as in the type. No papilla above isthmus.

Cosmarium Woodlawnense, n.sp. (Pl. xlii., f.8.)
Semicellulæ subtriangulares; basi plana (sinu lineari extrorsum ampliato); angulis basalibus rotundatis; lateribus levissime arcuatis, $5-6$ crenulatis, ad apices rapide convergentibus; apicibus angustis, levissime deplanatis, 4 crenulatis. Membrana hyalina, infra marginem serie granulorum, inter apicem et inter mediam semicellulain papillis 3 in triangulo dispositis, ornata. A vertice anguste-oblongæ, granulis minutis in seriebus transversis ornatæ; apicibus late-rotundatis; lateribus arcuatis; utrinque in medio papillis 3.

Long. 32, lat. 34, ap. 10 , isth. $10 \mu$.
Woodlawn, river.
The semicells are triangular, with flat base, and slightly depressed narrow apex. Across the sides, run 5-6 rows of minute granules, the margins and apex crenulate. Three large papillæ in a triangle between the apex and the middle of the semicell.

Cos. tholiforme Cohn.
Long. 100, lat. 75 , isth. $42 \mu$.
Lismore (185).
Cf. Cohn, Desm. Bongoenses, p.9, Tr. xi., f.9, semicell inferior. This desmid belongs to a small group of Cosmaria which have depressions in the membrane alternating with verrucæ. In this form, the markings on the membrane are arranged in vertical and decussating lines. They are of two kinds; the larger, with indistinct edges, appear to be depressions; the smaller, which focus sharply, smooth verrucæ. Cohn classes them all together as conical papillæ, but the markings on the upper semicell of his figure seem to contradict this. The depressions are first triangular, then irregularly hexagonal, finally circular.

Genus Euastrum Ehr.

> Eu. sinuosum var. campanulatum mihi.

Long. 100, lat. 55-57, ap. 20-21, isth. $12 \mu$.
Lismore (185, 240).
Syn., Eu. campanulatum Playf., Desm. N.S.W., p.176, Pl. iii., f. 16 .

Eu. turgidun var. Moebil (W. \& G. S. West) Playf.
Long. 114, lat. 95, lob. apic. 74, isth. $32 \mu$.
Lismore (185, 250).
Syn., Micr. Möbii W. \& G. S. West, Desm. Singapore, p. 162. The figures of Eu. turgidum Wallich, Desm. Bengal, T.14, f.17, 18 , show that the type has a simple apical lobe (not bifid at each side as in var. Möbii), Wallich's side-view agrees exactly with mine (for var. Auburnense Playf.) in Some Sydney Desm., Pl. xii., f.2. In forms with bifid apical lobes, the apex, in sideview, is much broader.

## Genus Micrasterias, Ag. <br> Micrasterias tropica Nord.

Long. max. 125, centr. 114; lat. max. 100, lob. pol. 44, coll. 20, isth. 18; crass. $33 \mu$.

Lismore (185).

Cf. W. \& G. S. West, Alg. fr. Burmah, Pl.14, f.23, and Nordstedt, Desm. C. Braz., Pl.2, f.15b. Micr. tropica is a form of M. Mahabuleshwarensis with a single lateral lobule. Raciborski's three forms, Desm. Tapakoomasees, f.7, 15, 16, also belong to that species. The forms with two lateral lobules are the direct outgrowth of those with one, and those with three are developed from those with two. The peculiar polar lobe with its apical prolongations is characteristic, and every Micrasterias having such belongs, biologically, to the same species. M. euastroides Joshua, Burmese Desm., Pl.22, f.14, is another variant of $M$. Mahabuleshwarensis, and its $\beta$ indivisa Nord., might, from the point of view of its form alone, be placed under M. tropica. Having regard, however, to the variability of all these forms, and especially of M. Mahabuleshwarensis, it is perhaps better to keep them as three distinct conventional types.
M. Mahabuleshwarensis var. ampullacea (Maskell) Nord.

Long. max. 174, centr. 142; lat. max. 154, lob. pol. 86, coll. 28, isth. $22 \mu$.

Lismore (187, 193).
Micr. ampullacea Maskell, 'Trans. N.Z. Inst., 13, Pl. xi., f.6, 7, differs only from M. Hermanniana Reinsch, Spec. generibusque, Pl.2, f.B, in having the three lateral lobules thicker, shorter, and more stumpy. A form with the third lateral lobule just started, as figured by Hardy, Vict. Natural., 1905, f.3, is common in this country, and is found here in the river along with the fullgrown form.

## Genus Xanthidium Ehr.

Xanthidium inchoatum Nord.f. (Pl. xlii., f.9a.)
Long. semic. 18, lat. 32, isth. $8 \mu$. Spinis nullis.
Lismore (240).
Cf. Nordstedt, Frw. Alg. N.Z., 1888, Pl. 4, f. 30a, semicell. superior. Synonyms of Xan. inchoatum are Ar. Incus Bulnh., Desm. Sachs., Pl.ix., f.3; Ar. Incus forma a, Lund., Desm. Suec.; Ar. Bulnheimii Rac., Desm. Nowe, 1889, p.23, T. ii., f.17; $A r$. Incus, "large form," Wolle, Desm.U.S, Pl.24, f.1.

## Var. mammllatum Playf. (Pl. xlii., f.11b.)

Long. semic. 20, lat. 40, isth. 6, ap. 28, basis $25 \mu$. Lismore (240).
Cf. Some Sydney Desm., p 619, Pl. xii., f.6.
Var. Cracoviense (Rac.) mihi. (Pl. xlii., f.9b, 10.)
Forma semicellulis Cos. psendoprotuberanti similibus, latioribus autem; sinu lineari, aut angusto introrsum ampliato; angulis superioribus magis subapicalibus.

Long. 36-44, lat. 32-44, basis 20-24, isth. $8 \mu$.
Lismore (240). Cum prioris duabus.
Syn., Cos. contractum var. Cracoviense Rac., Desm. Polon., p.28, T. x., f.10. Found also as a mixed form with $X$. inchoatum, f., supra. However much this may resemble Cos. pseudoprotuberans, it is quite certainly a spineless form of $X$. inchoatum, produced, as were the forms with it, by repeated self-division. We are here faced by a serious difficulty in the nomenclature, viz., what to do with these pseudo-Cosmaria, a large number of which are included in the genus Cosmarium, but are, biologically, forms of Xanthidium, and can be found as formee mixtce with semicells of that genus.

Var. a lpinum (Rac.) mihi. (Pl. xlii., f.11a.)
Long. semicell. 18, lat. 38, basis 25, isth. $6 \mu$.
Lismore (240). Cum precedentibus quattuor.
Syn., Cos. pseudoprotuberans var. alpinum Rac., Desm. Polon., p.27, T. x., f.11. The latter is very much smaller (long. = lat. = $10 \cdot 5-12 \cdot 5$, isth. $6 \cdot 5 \mu$, Rac.), but agreeing so exactly in shape with our form that I thought it best to accept the name. The equality of length and breadth also is characteristic of Xan. inchoatum and its forms.

## Genus Staurastrum Meyen.

St. tonsum (Nord.) mihi.
Long. 46-54, lat. 70-88, bas. infl. 18-20, isth. $11 \mu$.
Lismore (185).
Syn., St. pseudosebaldi* tonsum Nord., Frw. Alg. N.Z., p.36, T.4, f.4. The form agrees almost exactly with the lower semicell of Nordstedt's specimen. Others with more slender
processes were noted also. The inflation in the centre of the semicell shows that it is a reduced form of St. assurgens. The formae immaturae figured by me, Desm. N.S.W., p.192, Pl.v., f.31, are very similar forms; the dimensions there given, viz., long. 36-42, lat. 50-70, taken with those above, exactly tally with Nordstedt's.

Genus Onychonema Wallich.
Onychonema filiforme (Ehr.) R. \& B. Bisset. (Pl. xli., f.20.)
Long. cell. 12-16, lat. 16-22, isth. 2-3 $\mu$.
Lismore (185).
Syn., Sphcerozosma filiforme (Ehr.) Ralfs; Onych. Nordstedtianum I'urner, Alg. E Ind., p.139, Pl.17, f.17. Forms, much broader than generally given, were observed. Filaments are occasionally seen with the cells separated from one another, attached only by the tips of the clasper-processes.

Onychonema leve var. micracanthum Nord. (Pl. xli., f.21.)
Long. cell. 20, lat. $30 \mu$.
Lismore (185).
Cf. Nordstedt, Desm. C. Brazil, T.3, f.34; Alg. Lugd.-Bat., p.3. This species is, biologically, the fully developed form of $O$. filiforme.

## PROTOCOCCOIDE $※$.

## Fam. VOLVOCACEむ.

Genus Chlamydomonas Ehr.
Including Chloromonas Gobi. Gobi has segregated forms of Chlamydomonas which have no pyrenoids, into the genus Chloro. monas. But, in all the Protococcoidece, the presence or absence of pyrenoids depends entirely on the nutrition of the cell. Moreover, even when absent, the pyrenoids are often represented by a greater or less number of scattered, irregularly-shaped, amylaceous granules which seem to carry on the functions of a pyrenoid.

Chlamydomonas globulosa Perty. (Pl. xlii., f.12.)
Diam. 14-28 $\mu$.
Lismore (236, 237, 242, 244, 247, 253, 258).

Chl. pulvisculus Stein (non Ehr.), Flagellaten, Pl. xiv., f. vii.; Chl. Pertyi Goroschankin, Chlamydomonaden, Pl. ii., f. 13. Spherical, generally without anterior papilla, pyrenoid circular, quadrate or transversely oblong. Occasionally, the enveloping membrane grows faster than the body, and shows as a rim all round. Mother-cells with 4, more rarely 8, autospores observed. Goroschankin, quoting Rabenhorst, gives the diameter as $32-42 \mu$; the dimensions of our specimens are just half these figures. Wille, Gatt. Chlamyd., p.150, gives diam. 9-22 $\mu$, generally $14 \mu$.

Chiamydomonas monadina (Ehr.) Stein. (Pl. xlii., f.13.)
Diam. $26 \mu$.
Lismore (248). With Chl. globulosa (258).
Syn., Chl. Braunii Gorosch., Chlamyd., T. xiv., xv. Spherical, generally without a papilla, pyrenoid band-shaped. Probably a form of Chl. globulosa Perty. Cf. Stein, Pl xv., f.39. Very much rarer than the foregoing.

## Chlamydomonas intermedia Chodat.

Long. 20, lat. $15 \mu$.
Lismore (242).
Oval or oblong-oval in shape, generally without papilla. Cf. Chodat, Hist. d. Protococc., Pl. 22, 23; Wille, Gatt. Chlamyd., T.iv., f.155 ; Playfair, Syd. Water-Supply, Pl.57, f.14, 15 (size $13 \times 10 \mu$ ). Chodat, Alg. Vertes, p. 135 , gives dimensions(length?) 18-20 $\mu$.
Chl. gleocystiformis var. australis, n.var. (Pl. xliv., f.10.)
Membrana oblonga, hyalina; cellula ipsa ovata, fronte angustata, pyrenoidibus singulis sphæricis.

Membr. long. 20, lat. 14; cell. long. 12, lat. $9 \mu$.
Lismore (230).
Cf. C'hl. glceocystiformis Dill, in Chodat, Alg. Vertes, p.133, f.61-ix., and in Wille, Algol. Notizen xi., T. iv., f.17. I observed the type in Sydney. Bernard notes it from Java.

Chl. pisiformis Dill. (Pl. xliv., f.11.)
Long. 20-25, lat. 12-13, papill. long. 1-2, lat. $2 \mu$.
Lismore (236).

Cf. Dill, Chlamyd., p.14, T.5, f.13-19; Wille, Gatt. Chlamyd., p.138, T. iv., f.8. The latter gives dimensions, long. 18-24, lat. $11-14 \mu$. The papilla in this species is apt to mislead. From the front, it is sometimes very indistinct, showing as a short truncated cone, but, from the side, it is quite evident and appears as a short, rod-like projection (long. 1-2, lat. $1 \mu$ ) unlike that of any other species. All the forms of Chl. pisiformis were alike in this respect.

Var. cylindracea, n.var. (Pl. xliv., f.12.)
Cellulæ oblongæ vel cylindraceæ nec postice attenuatæ; angulis rotundatis; ceteris ut in f. typica.

Long. 16-26, lat. 11-16 $\mu$.
Lismore (236, 246, 247, 248, 260).
Probably the mature form of the type, which is more or less cylindrical in front but attenuate behind. As in all species of Chlamydomonas, the pyrenoid is sometimes wanting. This form is too short for Chl. grandis Stein, Flagellaten, Pl. xv., f.47, 49, (long. 28-40, lat. 8-12 $\mu$ in Wille, l.c., p.146) which is the only strictly cylindrical species, and which besides has two pyrenoids to the cell. From Chl. Steinii Goroschankin, (founded on Stein's Chl. grandis, Pl. xv., f.48, cf. Goroschankin, Chlamyd, Pl, ii., f.1, 2) it is distinguishable by the absence of the longitudinal ridges in the chloroplast.

Var. ovalis, n.var. (Pl. xliii., f.1; Pl. xliv., f.13.)
Forma ovalis; ceteris ut in f. typica.
Long. 16-22, lat. 12-17 $\mu$.
Lismore (236, 247). Wyrallah. Cum priori.
Var. obesa, n.var. (Pl. xliv., f.14, 15.)
Forma oblonga præ longitudine latior, angulis late-rotundatis; ceteris ut in f. typica.

Long. 12-22, lat. 10-16 $\mu$.
Lismore (236, 248, 260). Cum prioris duabus.
This and the preceding form are certainly growing forms of the type.

> Chl. DeBaryana Gorosch., f. (Pl. xliv., f.16.)

Long. 14, lat. $12 \mu$. Pyrenoidibus nullis visis.
Lismore (236).

Cf. Gorosch., l.c., p.106, Pl.i., f.9; Wille, l.c., p.141, T.iv., f.14. Chl. De Baryana is ovate, with a large protruding papilla in front; long. $12-20 \mu$ Gorosch. As found here, it is certainly a young growing form of Chl. pisiformis Dill.

Genus Carteria Diesing.
Cartbria ovata, n.sp. (Pl. xliv., f.17.)
Cellulæ ovatæ fronte late-rotundatæ non excavatæ, postice attenuatæ acutæ; chloroplastidibus non observatis; endochromate denso granulato; pyrenoidibus (ut videtur) nullis.

Long. 16, lat. 12, flagell. 4, circa $15 \mu$ long.
Lismore (259).
Obtained, as usual in this genus, from rainwater pools, in some quantity.

## Genus Pteromonas Seligo.

Pteromonas alata var. australis, n.var. (Pl. xlii., f.14)
Cellulæ ipsæ ovatæ, fronte attenuatæ acuminatæ, postice laterotundatæ. Membrana investiens, tenuis, hyalina, modice rectangularis lateribus parallelis, a tergo latissime rotundata angulis nullis, a fronte medio producto atque angulis etiam. Endochroma densum, granulatum.

Membr. long. 21, lat. 16; cell. long. 18, lat. $12 \mu$.
Lismore (247).

## Genus Phacotus Perty.

Phacotus rectangularis, n.sp. (Pl. xlii., f.15; Pl. xliii., f.2.)
Cellulæ a fronte visæ circulares; margine scabra; papilla parva inter setas duas; jugis humilibus arcuatis 3-4 decussatim dispositis ornatæ; a latere rectangulares apicibus truncatis; lateribus levissime arcuatis jugis humillimis 3 notatis. Membrana aspera, dilute luteola. Autosporæ ovales.

Long. $=$ lat. $=18-22$; crass. c. $10 \mu . \quad$ Cell. matric. long. 22, lat. $24 \mu$.

Lismore (244, 246).
Differs from Ph.lenticularis (Ehr.) Stein, and Ph. Lendneri Chodat, in its rectangular side-view, and the more or less regular curved ridges across the face. Cf. Chodat, Alg. Vertes, p.147, f. 71,72 .

Phacotus reticulatus, n.sp. (Pl. xlii., f.16.)
Cellulæ a fronte visæ circulatæ; margine glabra; papilla humillima inter setas; membrana inæqualiter reticulata, colore dilute rufescente; a latere ovales (ut videtur).

Long. $=$ lat. $=22 \mu$.
Lismore (246)
The lenticular form of the type is only a specific distinction, and not characteristic of the genus.

Genus Gonit m Müller.
Gonium pectorale Müller.
Cœn. long. 40, lat. $44 \mu$.
Lismore ( $236,237,239,260$ ).

## Genus Pandorina Bory.

> Pandorina morum (Müll.) Bory.

Con. long. 31-36, lat. 25-32 $\mu$.
Lismore (221, 237, 244, 246, 249).
Var. тнорісА, n.var. (Pl. xliv., f.18.)
Forma magna, cenobio ovali ; cellulis magnis conicis disjunctis.

Cœn. long. 52-70, lat. 44-60; cell. diam. 9-14 $\mu$.
Lismore (242).
Our Australian specimens of Pandorina morum seem to differ somewhat from the European. G. S. West, Br. Frw. Alg., p.192, says: "The cœnobia are spherical or subspherical . . ." and, with this, his fig. 76 A agrees. So also Chodat, Alg. Vertes, p.150, "Colonies globuleuses ou subglobuleuses . . . ." and his fig.58, xi., p.123. Our forms are invariably oval, cf. Stein, T.xvi., f.14, 15; I have never seen a spherical specimen. Var. tropica is rare, twice as large as usual, and the cells more isolated. The latter are arranged in three layers, whose planes are parallel to the long axis of the conobium, viz., a central ring of 10 , above and below which is a rosette of $6+1$. The cells do not reach the centre. Were it not that the sexual reproduction and germination of the zygotes are reported to be different (G S. West, l.c., pp.193-4), I should consider var. tropica to be an intermediate
form between the two genera Pandor na and Eudorina, especially since the oval form of Eudorina (very rare here) was found in company with $P$. morum var tropica in the same gathering (both in profusion).

## Genus Eudorina Ehr. <br> Eudorina elegans Ehr.

Cœn. ovale, long. 110-128, lat. 95-110, cell. diam. 20-22 $\mu$. Con. sphæric. diam. ad $100 \mu$.

Lismore (223, 241, 242, 249, 260).
Eudorina elegans here is generally spherical. In sample No. 242 , however, the oval form was present in company with $P$. morum var. tropica, supra, and showing a great likeness to it. The cells were certainly globose, but were arranged $(7+10+7)$ in three planes parallel to the long axis of the cœnobium (as in Pandorina), not across the axis as shown by Chodat, l.c., p.151, f. 76 A .

## Volvulina, gen.nov.

Character idem ac speciei.

> Volvulina Steinir, n.sp. (Pl. xliii., f.3, 4.)

Cœnobium sphæricum vel ovale, cavum, Volvoci simillimum; integumento tenui, hyalino, membranaceo (ut videtur) nec mucoso; intus cellulis æqualiter dispersis, integumento adhærentibus instructum; cellulis tholiformibus magnis, a vertice circulatis, a latere semicirculatis vel rotundato-conicis, fronte planis, postice rotundatis; stigmate rubro distincto juxta flagella posito; flagellis distinctis 2 quam in Volvoce vel in Éudorina paullo latius inter se distantibus; vesiculis contractilibus aliquot (3 visis) circa marginem anteriorem dispositis. Cytoplasma densum, granulosum; endochromate dilute viridi in granulis minutis ut videtur disperso; chloroplastidibus nullis distinctis nec pyrenoidibus.

Cœnob. sphær. diam. 50-58; cell. diam. 10-15, alt. 8-12 $\mu$.
Lismore (244, 246).
Eudorina elegans Stein (non Ehr.), l.c., T. xvi., f.8. Obtained in abundance on June 26th, 1914,(winter) from rainwater pools on grassland (once a swamp, I am told) alongside the Drill

Hall. Stein's figure would seem to suggest a mucous investment; probably, however, it is merely an incrassate membrane. The integument of our specimens is quite thin, and appeared to be membranous. Stein gives two contractile vesicles at the base of the flagella, as in Chlamydomonas; but my observations showed several, at least three, at intervals round the anterior margin. The flagella, also, were more widely apart than I have ever seen them in any bi-flagellate form. The difference in the cell-contents is merely a matter of nutrition. A central nucleus, $\times 3 \mu$, was noted.

Var. subreniformis, n.var. (Pl. xliii., f.5, 6.)
Cellulæ subreniformes, fronte planæ, a tergo subreniformes depressæ, in conobii ambitu circa 12-15; ceteris ut in f. typica.

Cœn. subsphær. long. 88-126, lat. 78-94; sphær. diam. 110-114; cell. diam. 10-14, inter se distant. 6-8 $\mu$.

Lismore (246).
Cf. Eudorina elegans Stein, l.c., T. xvi., f.9, peripheral cells. This form was gathered in abundance from the same place as the type, but a month later (July 8th, 1914).

Var. parvicellula, n.var. (Pl. xliii., f.7-9.)
Cœnobium plerumque minus interdum minimum; cellulis ut in f. typica vel in var. subreniformi sed minoribus.

Cœn. subsph. long. 64-100, lat. 60-90; cell. diam. 6-8 $\mu$.
Con. sphær. diam. 20-64; cell. diam. 5-6, inter se distant.8-12 $\mu$. Lismore (244, 246).
This variation was formed to include the small spherical cenobia with cells $\frac{1}{3}$ size of the type, of which any quantity were observed, of all dimensions. Cœnobia were occasionally noted, however, of almost the largest size, with cells just as small; and both in cœenobia, and in cells, a complete series was exhibited, from the very smallest to the very largest. Cells of two sizes were often present in the same conobium.

Var. lenticularis, n.var. (Pl. xliii., f.10.)
Cellulæ paucæ, latissimæ, lenticulares, integumento intus adhærentes; ceteris ut in f. typica.

Lismore (244).

This interesting flagellate combines, in itself, some of the characteristics of Volvox, Eudorina, and Chlamydomonas. The likeness to Volvox is more apparent than real. The organism looks, at first sight, exactly like a minute Volvox, with relatively large cells. No trace of parthenogonidia was observed, however, which are almost always present in Volvox, and the construction of the cœnobium is entirely different. The latter is hollow, and built up of a single layer of Chlamydomonadine cells of the Pteromonastype, having a loose membranous investment. These are so closely adpressed as to show, generally, a regular even margin in optical section; but cœnobia were observed (Pl. xliii., f.11) in which the component cells had worked loose, the cœnobium being glœocystiform and irregular at the edge. The peripheral cells, however, have the same relative position to the membrane as in the type-there is no integument to the coenobium other than the loose investing membrane of the cells. In this, Volvulina differs from Eudorina and Pandorina. Nevertheless, it is like them in its vegetative multiplication. Each cell, when mature, forms an 8-16-32-celled daughter-cœnobium. The latter are set free by the breaking up of the mother-cœnobium, and the solution of the membrane of the mother-cell. Such broken cœnobia were noted (cell. matric. diam. 36, cœn. filial. 24, cell. 3-4 $\mu$ ) in which it could be noted that there was a single layer of cells without any investing mucus or membrane.

## Genus Volvox (Linn.) Ehr. <br> Voi.vox tertius Meyer.

Syn., Volvox Bernardii Playf., Biol. Richm. R., p.106, Pl. ii., f.5-11. Too late for correction, I came across a casual note by Lemmermann in Plankt. Schw. Gewäss., p.105, on Volvox. He says, " $V$. aureus Ehr., and $V$. tertius A. Meyer, ${ }^{*}$ seem in many ways to be interchangeable with one another, as they both possess round cells; these in V. aureus Ehr., are connected with one another by protoplasmic threads, in $V$. tertius A. Meyer, on the other hand, they are not." As the absence of these threads is

[^4]characteristic of $V$. Bernardii, it is evident that the latter must be identical with $V$. tertius Meyer.

While there is no doubt that, biologically, $V$. aureus and $V$. tertius belong to the same species, since their zygotes are identical (vide infra), the latter seems to be a distinct permanent varicty, and worth keeping separate (as a conventional species) for that reason, and also on account of the forms connected with it. In Europe, it would appear that $V$. aureus is common, while $r$. tertius is hardly known. Neither Chodat in Alg. vertes de la Suisse, 1902, nor G. S. West, Br. Frw. Algæ, 1904, mention the latter, nor have I seen any reference to it. On the other hand, in this country, to judge at any rate from the Richmond River district, $V$. aureus is very rare (I have only one record of it), while $V$. tertius is common and widespread. It is probably a permanent tropical and subtropical variety.

Cœn. sphær. diam. 214, 220, 300, $320,325,360,450,500,635$, $700,800,950$; membr. crass. $2-8$, vulgo $2-3 \mu$; cell. diam. 5-8, plerumque 8 , inter se distant. $5-20 \mu$. Cœn. filial. sphær. diam. ad 250 , rarius oval. long. 123-247, lat. $105-180 \mu$, numero 2-10 plerumque 6-8; cell. diam. $4 \mu$. Oosporæ (usque ad 17) diam. $30 \mu$.

Lismore (223, 241, 249, 259, 260, 261 ), Wyrallah, Kyogle.
Var. ovalis, n.var. (Pl. xliv., f.4.)
Cœnobium ovale vel oblongum, paullo minus; cœnobiis filialibus paucis; plerumque ovalibus vel oblongis.

Cœn. long. 114-475, lat. 101-425; cœn. membr. crass. 2-4 $\mu$; cell. diam. 4-8 plerumque $6 \mu$. Cœn. filial. long. 86-114 $\mu$ (numero 1-5). Oosporæ (numero 9-20) diam. 42-55, membr. crass. 3-4 $\mu$. Androgonidia immatur. diam. 10-15, matur. diam. 20-22. Antheroz. long. 8-10, lat. $2-2 \frac{1}{2} \mu$.

Woodburn (227), Lismore (241, 259).
A very rich gathering of this form was brought me by Mr. Dan Jolly from a lagoon at Woodburn. On examining the cœnobia in the living state with the aid of a Coddington lens, it was noticeable that, in a large majority of cases, the specimens were smaller than usual and quite distinctly oval or oblong, as also were the daughter cœnobia. The number of the latter also in the mother-conobium was less, $2-3$ were common, 4 were frequent,
and in no case were there more than 5. Male, female, and vegetative cœnobia were observed. The oospores correspond exactly to the description given for $V$. aureus by Overton, Gatt. Volvox, p.33, (V.minor), and by Janet, Le Volvox, p.99. They are smooth, with a thick outer and thin inner membrane, and (apparently) a mucilaginous packing between the two. The membrane is first hyaline, then yellow, orange, and finally redbrown (Pl. xliv., f.4).

```
Var. guttulosa, n.var. (Pl. xliv., f.1.)
```

Cellulæ subpyriformes, postice subglobosæ, fronte in rostro angusto acuto productæ; stigmate rubro in extremo rostro posito; cytoplasmate granuloso, chloroplastibus etiam; pyrenoidibus nullis, granulis autem paucis magnis.

Cell. long. max. 16, rostra. ca. 6; cell. lat. max. 6, ap. $1 \frac{1}{2} \mu$. Cell. inter se distant. $12 \mu$. Cœn. integum. crass. $6 \mu$.

Lismore (250).
A very rare form, interesting, however, as showing how the cells may vary in shape.

Var. tessellata, n.var.
Cellulæ a vertice visæ dense congregate, inter se distantes $1-2 \mu$, interdum fere contiguæ, ambitu inæqualiter orbiculatæ, subpolygoniæ, dimensionibus variis.

1. Con. matric. diam. 475-600; cell. diam. 2-6 vulgo $4 \mu$. (Pl. xliv., f 2.)

Lismore (242).
2. Cœn. filial. diam. 180; cell. diam. circ. $3 \mu$. (Pl. xliv., f.3.)

Lismore (242),
This form is found both in the free mother-cenobia and in daughter-ccenobia; in the latter case, the mother-cenobium very often conforms to the type. The variation was plentiful in No. 242, a gathering taken out of roadside rainwater-pools on June 2nd, 1914, (winter) after heavy rains.

Vohvox (ilobator (Limn.) Ehr. (Pl. xliv., f.5, 6.)
Cøen. diam. 450.600; integum. crass. 1-8: cell. diam. 4.6, vel 6-8, tilis connect. crass. ca. $1 \mu$, inter se distant. $2-3 \mu$. Zygotee,
numero circ. 200, diam. max. 50-60, cell. diam. 34-36, membr. s.sp. circ. 3 , spin. long. ad $8 \mu$.

Lismore (260, 261).
$V$. globator is only a little less rare in the district than $V$. aureus. The cells, of the specimens I have noted, did not show as distinctly stellate as the European forms, and as figured in Overton, Gatt. Volvox, T.i., f. 4, rather than in Klein, Gatt. Volvox, 1889, T. x., f.2, or in Janet, Le Volvox, p.39, f.3. The connecting filaments (for they can hardly be termed arms) are very faint and indistinct, and not more than $1 \mu$ thick, hyaline; while the cells are very irregular in outline, but apparently more compact than in European specimens, and rather closely packed. The chloroplast is sometimes pale yellow-green, but just as often the same pale green colour as in $V$. aureus. The oospores are yellow or green, with a hyaline integument consisting of an inner and an outer membrane separated by a mucous zone, the outer membrane covered with conical spines somewhat longer and more pointed than generally figured.

Var. australis, n.var.
Cœnobium cellulis a vertice visis inæqualiter polygoniis, densissime ordinatis indiciis filorum solis cernendis; cellulis a latere (sectione opticali) globosis. Chloroplastides dilute virides.

Cœn. diam. 500; cell. diam. 3-4, vel 4-6, inter se distant. $1 \mu$.
Lismore ( 261 ). Cum priori.
This form is almost indistinguishable from $V$. tertius var. tessellata; the cells are of the same colour, globose in sideview, very closely packed, almost touching in places, and the connecting strands are absent. The cells, seen from above, however, are, in this variation, a little more irregular in outline, and here and there, at the angles, a slight point indicates the position of the missing filaments.

## Volvox Lismorensis, n.sp. (Pl. xliv., f. 7, 8.)

Cellulæ a vertice visæ inæqualiter polygoniæ nec stellatæ, filis tenuissimis, sæpe inter se reticulatis, conjunctæ; stigmate rubro distincto. Cellulæ a latere ut in V. globatore, pyramidales, a tergo pæne planæ, angulis lateralibus productis, filis tenuissimis
conjunctæ, stigmate ad apicem. Chloroplastides luteo-virides, pyrenoidibus nullis visis.

Con. diam. 790; cell. diam. 8, inter se distant. $20 \mu$. Cœen. filial. diam. 215-275, cell. diam. 6, inter se distant. $2 \mu$.

Lismore (250).
This species resembles $V$. globator in the colour of the chloroplasts, and in the shape of the cells in optical section. From above, however, the cells are not stellate, but only irregularly polyhedral, with a minute point at the angles sometimes. They are connected by extremely delicate threads, much more delicate than in $V$. aureus, sometimes hardly visible. Generally, the threads are double, rarely triple, and, instead of running directly between the cells, they have a habit of anastomosing with one another.

Var. globulifera, n.var, (Pl. xliv., f.9.)
Cenobium cellulis a vertice inæqualiter polygoniis, filorum indiciis solis raro cernendis; cellulis a latere globosis.

Cœn. diam. 290-500; cell. diam. 7-8, inter se distant. 6-20 $\mu$. Cœn. filial. diam. 150, cell. diam. circ. 8, partic. ultim. circ. $3 \mu$.

Lismore (250). Cum priori.
The cells, from above, are irregularly polygonal, with the angles occasionally drawn out a little; here and there, but only rarely, one of the very delicate filaments might be noted. In sideview, the cells are globose. A figure (Pl. xliv., f.9) is given of the surface of one of the daughter-conobia; the cells were large, $8 \mu$ in diameter, and indistinctly outlined with smaller cells of many shapes and sizes between. The large cells seemed to be fragmenting into $4-6$ smaller cells, $3 \mu$ in diameter-the "partic. ultim.", supra.

Genus Hydrodictyon Roth.
Hydrodictyon reticulatum (L.) Lag.
Cell. long. 200, lat. centr. 32, ap. $40 \mu$.
Lismore (255).
Genus Ineffigiata W. \& G. S. West. Ineffigiata neglecta W. \& G. S. West.
Small pieces, up to diam. $90 \mu$, plentiful, of a brownish- or yellowish-green colour.

Lismore (185, 223, 260, 261).
Botryococcus Braunii very rare, only just recorded.
[For genus T'rochisia, see Appendix, under Clyytridiacece.]

## BACILLARIE $\mathbb{E}$.

Genus Amphora Ehr.
Amph. Lagerheimil var. minuta, n.var. (Pl. xlv., f.8.)
Forma minima, striis nullis visis.
Long. 15-20; lat. frust. 7-9, ap. 3; lat. valv. 4-5 $\mu$.
Lismore (211).
Cf. A. Lagerheimii Cleve, Diatomiste ii., p.99, Pl. vii., f.2; Synopsis ii., p.118. The latter is a very rare form, known only from Ecuador. Characteristic of the species is the short, stauriform mark in the centre of the dorsal margin. The type measures $50-70 \mu$ in length, and was obtained from rocks moist with fresh water. Var. minuta was found, alive, in some quantity, in a mucous stratum of Phorm. corium, at the edge of an open concrete water-table in Carrington Street. The chloroplasts were very distinct, with four minute elæoplasts as figured.

## Genus Stauroneis Ehr.

Stauroneis fulmen Brightwell. (Pl. xlv., f.9.)
Long. 114-196; lat. valv. 30 , subapic. circ. 12 ; crass. frust. $30-33 \mu$. Lismore (185, 240, 249).
Known only from Java, Australia, and New Zealand. Cf. Brightwell, Micr. Journ., vii., p.180, Pl.ix., f.6. Widespread in swamps throughout this country. There is a double columella, with a true raphe (undulate) in the space between. Cleve, Syn. i., p.150, gives this form as capitate. I have never noted it, however, with more than a rostrate apex. Here, the apices are exactly those of Staur. acuta. of which Cleve considers it a variety.

Genus Pinnularia Ehr.
Pinn. streptorapie var. gibbosa A. Cleve. (Pl. xlv., f.10.)
Long. 140, lat. $20 \mu$. Striæ 7 in $10 \mu$.
Lismore (185).

Cf. Astrid Cleve, Diat. Lule Lappmark, p.6, T. i., f.1; P. T. Cleve, Diat. Finland, p.23. Ends conical, frustule only very slightly inflated in the middle. P. T. Cleve gives striæ 5 in $10 \mu$; A. Cleve, 7 in $10 \mu$.
P. divergens var. elliptica (irun. (Pl. xiv., f.11.)

Long. 70 , lat. $16 \mu$. Striæ 7 in $10 \mu$.
Lismore (185).
Grunow, Diat. Fr. Josefs Ld., p.98, Pl.i., f.19; Cleve, Syn. ii., p. 79 ; the latter gives $75 \times 15 \mu$, strix 8-10 in $10 \mu$. The larger sizes of $P$. Brébissonii type and the smaller of $P$. divergens var. elliptica seem to be identical in appearance, cf. Lagerstedt, Diat. Spetsb., Pl. i., $\mathrm{f} .2 a$, which is accepted by Cleve as P. Brébissonii; the figure gives long. 62 , lat. $17 \mu$

Genus Navicula Bory.
Navicula subtilissima Cleve. (Pl. xlv., f.12.)
Long. 38 , lat. 8 , ap. $5 \mu$.
Lismore (185).
Syn., Stauroneis linearis Lagerstedt, Sötr. Diat. Spetsb., 1873, Pl. ii, f.13. Cf. Cleve, Diat. Finland, 1891, Pl. ii., f.15, who gives $32 \times 5 \mu$; Lagerstedt, long. 30-34, lat. $7-8 \mu$. Nav. lineuris Grun., 1860, prevents the adoption of Lagerstedt's specific name. A rare diatom, known only from Lappland, Sweden, and Spitzbergen. There is a faint pseudostauros on either side of the central nodule.

## Diadesmis-forms.

N. confervacea var. peregrina (W. Sm.).

Long. 15-20; lat. valv. 8, crass. frust. 4-8 $\mu$.
Lismore (178, 187, 188, 190, 192, 193, 195, 197).
Diadesmis confervacea var. peregrina, Biol. Richm. R., Pl. v., f.25. The frustules are so strongly agglutinated together, that the filaments always break by the valves coming apart. The following species, which were also found in long ribbons, I have arranged as Diadesmis; but the ribbons seem of a different nature from those of Nar. confervacea, being very fragile; and,
in gatherings, the frustules are generally found separate, or in groups of 4-8.

Navicula minima Grun. (Pl. xlv., f.13.)
Long. 14-16, lat. valv. 5-6; crass. frust. $3 \mu$.
Navicula atomus Näg. (Pl. xlv., f.14, 15.)
Long. 6-9, lat. valv. 3-4, plerumque 4; crass. frust. $3 \mu$.
Navicula exilissima Grun. (Pl. xlv., f.16.)
Long. 10-14, lat. valv. 4-5; crass. frust. $3 \mu$.
Navicula Flotowii Grun. (Pl. xlv., f.17.)
Long. 14-22, lat. valv. 5-6, ap. 2-3; crass. frust. $3 \mu$.
Lismore, all four forms (178, 186); the last three (176, 178); Nav. atomus (176, 178, 186, 192, 196).

Cf. Van Heurck, Diatomaceæ, pp. 227-230, Pl.5, f.229, 231, 234, 238. Nav. Flotowii is the only one of these four that is recognised by either Cleve or Van Heurck as Diadesmis. Here, however, I find them all in long ribbons(diam.6, 8, 10, 11, 12, 13, $14 \mu$ in sample No.186). Also, they all exhibit a similar appearance under the microscope, and are all found in quantity associated together. There seems, therefore, to be some connection between them.

## Genus Vanheurckia Bréb.

Vanheurckia rhomboides (Ehr.) Bréb. (Pl. xlv., f.18.)
Long. 68, lat. 16, ap. circ. $4 \mu$.
Lismore (185).
Cf. Donkin, Brit. Diat., Pl. vi., f.11. A very rare form of the genus; this is only my second record of it. The other specimen, from the Sydney Water Supply, measured $90 \times 16 \mu$. The apex is simply rounded, not rostrate at all.

Vanh. vulgaris (Thw.) Van Heurck. (Pl. xlv., f.19-21.)
Long. 40-50, lat. 10-14, ap. 3-4 $\mu$.
Lismore (185).
Thwaites, Ann. Mag. Nat. Hist., Ser. 2, Vol. i., Pl.xii., f.H1-5. Not Van Heurck, Diatom., p.239, f. 39 ( $=$ V. viridula) nor Pl.5, f.252. Thwaites says "lanceolate, suddenly narrowed near the
apices," and his figures show a plump little frustule, not at all slender, elliptic-lanceolate, with sides well arched, not parallel, suddenly constricted near the ends into a short rostrate apex. Forms of this genus are common enough in the swamp-waters of this country, but I have never yet seen them in mucous tubes.

Var. Richmondie, n.var. (Pl. xlv., f.22.)
Forma fasciâ transversâ, usque ad margines valvæ non pertinente, utrinque ad nodulum centralem instructa.

Long. 54-58, lat. 12-14 $\mu$.
Lismore (185). Cum priori.
This form is more like those given for the type by Van Heurck.
Vanh. cuspidata var. ambigua (Ehr.) Cleve.
Long. 66-80, lat. 19-20, ap. 4-5 $\mu$.
Lismore (213, 221, 253).
Nav. ambigua Ehr., in Donkin, l.c., Pl. vi., f.5. Cleve, Synopsis i., p.109. This form is very like V. vulgaris, from which it may be distinguished by its larger size, and specially by a very slight angularity here and there in the arched sides. It is frequent at Lismore in waterholes and swamps, and in the mucous strata of the Myxophycece.

Forma.
Forma fasciâ transversâ utrinque ad nodulum centralem instructa.

Long. 76, lat. valv. 20, ap. 6; crass. frust. $10 \mu$.
Lismore (223).
Compare V. vulgaris var. Richmondice, supra. Genus Gomphonema Ag.
Gomph. lanceolatum var. insigne Greg. (Pl. xlv., f.23.)
Long. 62, lat. $10 \mu$. Striæ 8 in $10 \mu$.
Lismore (185).
Genus Acheanthes Bory.
Achnanthes Woodlawnensis, n.sp. (Pl. xlv., f.24.)
Frustula oblonga genuflexa, zona connectente per longitudinem striata, striis tenuibus 8-9. Valvæ lineari-lanceolatæ, in medio evissime inflatæ, apicibus conicis, transverse striatis. Valva
inferior lineâ centrali et fascia transversali instructa. Valva superior striata tantum, linea centrali nulla nec fascia.

Long. 84, lat. valv. 18, frust. crass. $24 \mu$. Striæ 8 in $10 \mu$.
Woodlawn (225).
I can find no description answering to this form, in Cleve's Synopsis. The stauros is $3 \mu$ broad.

## Achnanthes exigua Grun. (Pl. xlv., f.25, 26.)

Long. 13-16, lat. 6-7, ap. 3; frust. crass. $4 \mu$.
Lismore (176, 178, 190).
Cf Schumann, Preuss. Diat., Nachtrag ii, Pl.ii., f.59. 'This species was found, in some quantity, along with Nav. minima and its three companions (supra), and there was reason to believe that its frustules had been originally, like the others, in long filaments. Cleve, Syn., ii., p.190, gives dimensions, long. 13-17, lat. $5-6 \mu$. He places the species in a class of Achnanthes which, he says, has affinities with the groups of Navicula, including the four mentioned above. The chromatophores of all are of the same shape, so that it is highly probable that this form is really a Navicula, and that the Achnanthes-features are merely temporary. I could see no genuflexion in the sideview of the frustules.

## Achnanthes linearis $W$. Sm.

Long. 13-16, lat. 4 ; crass. frust circ. $3 \mu$.
Lismore (178).
Found in company with Ach. exigua, above, and the four small Diadesmis-forms of Navicula. I had a suspicion that the latter were occasionally to be found curved in girdle-view.

Genus Stenopterobia Bréb.
sten. anceps var. Heribaudi Playf.
Long. 105, lat. $6 \mu$.
Lismore (240).
These Proceedings, 1913, p.535, Pl.56, f.21. Syn., Sten. anceps Heribaud (not Lewis), Diat. Auvergne, Pl. v., f.4. Forms of Sten. anceps Lewis, ( = Nitz. franconica Rein.) are widespread in this country.

## MYXOPHYCE A.

Genus Anabena Bory.
Anabena oschllablohes Bory. (Pl. xlvi., f.1.)
Cf. Biol. Richm. R., p.127, for dimensions. Three shapes of gonidia were noted in this one sample, viz.: (1) oblong, with arched sides, and broadly rounded ends; (2) broadly cylindrical, with flat sides, and broadly rounded subtruncate ends; (3) long narrow cylinders, with straight sides, and truncate ends.

Lismore (185).
Genus Cylindrospermum Kütz.
Cylindrospermum rectangulare, n.sp.
Stratum obscure-viride. Trichomata pallidissime æruginosa, ad genicula constricta, apicibus conicis. Vagina tenuissima, distincte observata Cellulæ quadratæ vel cylindraceæ, disjunctæ, protoplasmate homogeneo vel minute granulato. Heterocystides ro-tundato-conicæ vel oblongæ subcylindraceæ; apicibus rotundatis. Gonidia stricte cylindracea, lateribus planis, apicibus truncatis; vel doliformia, lateribus levissime arcuatis, apicibus truncatis; vel rarius elliptico-lanceolata, apicibus rotundatis; protoplasmate granulato, dilutissime æruginoso pæne hyalino.

Trich. diam. 4-5; cell. alt. 6-10, sæpe $8 \mu$. Heterocyst. conic. long. 6-10, lat. 5-6, cylindr. long. 11-12, lat. $6 \mu$. Gonid. cylindr. long. 12-15, lat. 5 -6, doliform. long. 16-20, lat.7-8, lanceol. $22 \times 10 \mu$.

Lismore (256).

and of the gonidia. The trichomes and gonidia were very pale blue, almost hyaline. A delicate sheath was distinctly observed.

## Genus Plectonema Thuret.

Plectonema nostocorum Bornet.
Plentiful, much branched, almost hyaline, in a mucilaginous stratum with other Lyngbyere. I have never found this species pale yellow-green, as noted by Gomont, Monog. d. Oscill., p.103; but almost all the blue-green Lyngbyece have a yellow-green form.

Lismore (213).
Plectonema crispatum, n.sp. (Pl. xlvi., f.2.)
Stratum sordide olivaceum. Fila primum sessilia cæspitosa, deinde arcte intricata, abundanter pseudo-ramosa, pseudo-ramis solitariis, curvatis. Vaginæ distinctæ hyalinæ. Trichomata pallide æruginosa pæne hyalina, apicibus conicis, ad genicula haud constricta, protoplasmate homogeneo. Dissepimenta distincta haud granulata.

Trich. diam. 2-3, cell. alt. 1-2 $\mu$.
Lismore (210).
Found as a pinky-brown stratum on a zinc-footwasher at the Presbyterian Church. Other parts of the stratum, however, were dull green, and the purple colouration was found to be entirely due to inert vegetable débris. The trichomes themselves were very pale blue, almost hyaline.

## Genus Lyngbya C. Ag.

Lyng. erugineo-cerrulea (Kütz.) Gomont.
Trich. diam. 6-8, cell. alt. 2-4, plerumque $2 \frac{1}{2} \mu$.
Lismore (199).
Trichomes strongly blue-green; dissepiments very distinct, in the larger trichomes apparently minutely granulate; ends conical or rounded. Sheath noted.
Lyng. Kutzingii var. distincta (Nord.) Lemm. (Pl. xlvi., f.3)
Trich. diam. $1 \frac{1}{2}-2$, cell. alt. circa $1 \frac{1}{2} \mu$.
Lismore (201, 206, 211).

Cf. Lemmermann, Engl. Bot. Jahrb., 34, 1905, p.620. Syn., Lyngbya subtilis West, Alg. Lake Dist., p.29, Pl, x., f.58; L. Martensiana $\beta$ distincta Nord., Alg. Sandvich., p.4; L. circumcreta G. S. West, Third Tanganyika Exp., p.174, Pl.9, f.7. Trichomes pale blue, with homogeneous but generally opalescent protoplasm, so that the dissepiments are barely visible; occasionally, however, with translucent protoplasm, when the septa are distinct. The same occurs in $O$. splendida. The ce'ls are square or a little shorter than the diameter, the sheath very delicate, filaments often spirally twisted, apices truncately-rounded. Lyngbya circumcreta G. S. West, l.c., is a plankton-form of the species, the coiling of the filaments being a plankton-phenomenon of not infrequent occurrence (cf. Melosira granulata var. circinalis Playf., Syd. Water-Supply, p.536), and not of any specific value. It should be noted as confirmatory that this form was obtained from the same two localities as $L$. Kïtzingii var. distincta, l.c., pars.308. 309, at the same time of year.

## Genus Phormidium Kütz.

Phormidium uncinatum (Ag.) Gomont. (Pl. xlvi., f.4.)

1. Fila distincta, libera, vaginis haud agglutinatis. Dissepimenta plerumque haud granulata.

Trich. diam. 7-8, cell. alt. 2-4, vulgo 3-4 $\mu$.
Lismore (212).
2. Fila distincta, libera, vaginis haud agglutinatis. Septa granulata.

Trich. diam. 8, cell. alt. 4-5 $\mu$.
Lismore (230).
3. Fila distincta, libera, vaginis haud agglutinatis. Septa sæpe granulata. Trichomata omnia apicibus capitatis.

Trich. diam. 8, cell. alt. 4-6 $\mu$,
Lismore (252).
Oscill. uncinata Ag., Ph. uncinatum (Ag.) Gomont, Monog. d. Oscill., p.184, Pl. v., f.21, 22. Three, fine, mucous strata of this plant were obtained, not one of which, as stated above, was in the Phormidium-condition. The filaments were free, and
wandered about the field of view. The trichomes pale blue-green, transparent, attenuate, and curved at the tips; dissepiments distinct, sometimes smooth, sometimes granulate. A great variety of apices were noted, the prevailing types, however, being rounded, capitate, or with depressed conical calyptra.

Phormidium lucidum ( Ag ) Hansg. (Pl. xlvi., f.5.)
Fila distincta, libera; vaginis haud agglutinatis. Trichomata dilutissime reruginosa, ad genicula constricta, cellulis altioribus plerumque dissepimentis incipientibus instructis.

Trich. diam. 8-10; cell. alt. $2-3 \mu$.
Lismore (213) Cum sequenti intermixtum.
Var. amgenum (Kütz.) mihi. ( $\mathrm{Pl} . \mathrm{xlvi} ., \mathrm{f} .6$.)

1. Fila distincta, libera; vaginis haud agglutinatis. Trichomata dilutissime æruginosa semper pæne hyalina, ad genicula non constricta, apicibus conicis vel late-rotundatis, cellulis angustis, dissepimentis conspicuis haud granulatis.

Trich. diam. 5-6; cell. alt. $1 \frac{1}{2}-3 \mu$, interdum ad $1 \mu$ approx.
Lismore (213).
2. Fila libera. Trichomata saturate æruginosa, apicibus rotundatis subtruncatis, dissepimentis interduın minute granulatis, sæpe septis inconspicuis alternantibus. Cetera ut in f. precedente.

Trich. diam 8-10 (rarius 11); cell. diam. 3-4 $\mu$.
Lismore (213).
3. Fila glabra libera. Trichomata dilute æruginosa, ad genicula quam levissime constricta, apicibus rotundatis conicis, dissepimentis validis non autem granulatis.

Trich. diam. 6; cell. diam. 2-4, vulgo $2 \mu$.
Lismore (232).
Amphitrix amœenu Kützing, (pro parte) Tab. phyc i., p 45, T.79, f. 1 (sec. Gomont). Phorm. ambiguum Gomont, Monog. d Oscill., p.178, Pl. v., f.10. This is a form of Ph. lucidum without constricted joints. Not only are the two forms otherwise exactly alike in general characteristics, but, in sample No.213, I find them intermixed; and, in No.232, an intermediate form in which the constriction is rery faint, represented only by a minute
puncta-spot. In neither of these samples were the filaments in the Phormidium-condition.

Phormidium corium (Ag) Gomont. (Pl. xlvi., f.7.)
Trich. diam. 3-3 $\frac{1}{2}$; cell. alt. 3-8, vulgo $4 \mu$.
Lismore (205, 209).
Cf. Gomont, l.c., p.172, Pl. v., f.1, 2. Pale blue, generally transparent, with distinct dissepiments, protoplasm minutely granulate, sometimes a central body in the middle of each cell. Stratum membranous or coriaceous.

Var. acuminatum, n.var. (Pl. xlvi., f.8.)
Formæ typicæ consimile sed latius. Trichomata dilute viridia apicibus acute conicis.

Trich. diam. 5-8; cell. alt. 3-8, apical. 8-10 $\mu$.
Lismore (207, 211, 228).
First obtained from a roadside ditch near the Cathedral. Gomont gives diam. $3-4 \frac{1}{2} \mu$ for the type, cell. alt. $3-8 \mu$. Our specimens agree exactly with his details. In this form, the trichomes are green rather than blue, and the natural tips are acutely conical, in broken filaments (with projecting sheath) they may vary from simply rounded to bluntly conical Phorm. Crouani Gomont, l.c., p.175, is a still broader form of this species, diam. $7 \frac{1}{2}-10 \frac{1}{2}$, cell. alt. $4-8 \mu$; the description agrees perfectly with that of Ph. corium, and var. acuminatum just connects the two sizes. I do not see how Ph. papyraceum(Ag.) Gomont, l.c, p.173, Pl. v, f.3, 4, can be distinguished from Ph corium.

Var. constrictum, n.var. (Pl xlvi., f.9.)
Trichomata dilutissime æruginosa, ad genicula constricta, apicibus naturalibus acutissime conicis; cellulis cylindraceis, diametro ad duplum longioribus, protoplasmate minute granulato.

Trich. diam. 4- 5 ; cell. alt. $8 \mu$.
Lismore (228). Cum priori.
Trichomes about the size of the type, but distinctly constricted at the joints, and very sharply pointed; the cells cylindrical, not quadrate as usual in this species. All the forms of Ph. corium were true Phormidia, the stratum membranous, sheaths agglutinated.

Genus Oscileatoria Vaucher.
Oscillatoria princeps Vaucher (Pl. xlvi., f.10.)
Trich. diam. 28-44, ap. 18; cell. alt. 4-8 $\mu$.
Lismore (187).
Gomont, l.c., p.207, Pl. vi., f.9. Colour pale grey-green, protoplasm very finely granular, dissepiments not granulate. Specimens are often found with a very thick sheath, and there are indications of permanent septa across the sheath between the cells (Pl. xlvi., f.10c). Found only in the river here.

Oscillatoria Corakiana, n.sp. (Pl. xlvi., f.11.)
Fila lata, vaginis observatis. Trichomata subrubicunda vel atrochalybea, viridi tincta, interdum ad genicula constricta; apicibus leviter attenuatis rotundatis, aut arcuatis subtruncatis; cellulis angustis; dissepimentis conspicuis, granulatis; protoplasmate minute granulato.

Trich. diam. 11-12; cell. alt. 2-4 $\mu$.
Coraki (202).
The colour of the trichomes, a pale pinky-brown, or dark grey, flashed with pale green, seems to distinguish this species from all others. The trichomes are sometimes constricted, sometimes not; it is a character that I find to be of very doubtful value.

Oscillatoria formosa Bory. (Pl. xlvi., f.12, 13.)
Trichomata dilute cyanea vel dilute viridia, vulgo ad genicula constricta sed non semper, dissepimentis rarissime granulatis.

Trich. diam. 4-7; cell. alt 2-4 $\mu$ Vagina repetitim observata
Lismore (201, 206, 207, 208, 221, 226, 229).
Gomont, l.c., p.230, Pl. vii., f.16. Very frequent in the district; the smooth, rounded, uncinate tip cannot be mistaken The breadth is usually $5-6 \mu$, with cell. alt. $3-4 \mu$. The dissepiments are almost invariably smooth; in No.229, however, (a pure mucous stratum) the dissepiments have the appearance of thin lines, with $3-4$ very distinct granules strung on them.

Var australica, n.var. (Pl. xlvi., f.14.)
Trichomata dimensionibus et ceteris ut in forma typica, cellulis autem protoplasmate spisso, globo centrali colore pallido, ubique zonâ angustâ coloris saturatioris circumcincto.

Trich. diam. 4-8, vulgo 5-6; cell. alt. 2-4, plerumque 3-4 $\mu$. Lismore (202, 213).

The contents of the cells are peculiarly arranged in this form, giving it a distinct appearance. The protoplasm is opalescent, the central portion very pale and surrounded by a narrow zone slightly darker in colour.

Appendix on the Algal Fungi and Schizomycetes.
ALGAL FUNGI.
CHYTRIDIACE』.
Genus Chytridium A.Br. Chytridium grefiarium Nowakowski.

Filling the carapaces of dead rotifers, as usual. The identification is certain, and I have followed Nowakowski in the nomenclature; but it seems to me that this form is doubtfully placed under Chytridium.

Lismore (237, 244).

Fig. 1.
Chytridium gregarium; mature cell about to dehisce; ( $\times 665$ ).

## Chytridium amphoroidium Playf.

Olpidium amphoridium, e lapsu, Biol. Richm. R., p.137; Chytridium amphoridium, ibid., Pl. vii., f.5.

Lismore (220). On Macrothrix spinosa (Entomostraca).

## Chytridium gracillimum, n.sp.

Cellulæ gracillimæ, ensiformes vel fusiformes; apicibus acutis acuminatis; inferne lateribus ad bàsin acutam sensim sensimque convergentibus; stipite nullo nec pede. Cytoplasma hyalinum, granulatum, chloroplastidibus nullis. Membrana hyalina tenuissima.

Cell. long. ad 240; lat. 6-8 $\mu$.
Lismore (236) on Lemna; (249) on Moina propinqua (Entomostraca); (254).

Var. falciforme, n.var.
Cellulæ superne pulcherrime crispatæ.
Long. vertical. 90, lat. 54 ; cell.

Fig. 2. diam. $6 \mu$.

Lismore (236)
This species is very like Characium ensiforme Herm., (cf. G. S. West, Br. Frw. Alg., p. 200, fig.80D), but it has no stipes or expanded base, and no chlorophyllaceous contents. It is still more like Chamesiphon curvatus Nord., Alg. Sandvich., p.4, T.i., f.2, but the forms of Chancesiphon have a definite sheath of considerable thickness, enclosing a chlorophyllaceous core. The membrane in Chytridium gracillimum is very thin, is not of the nature of Chytridium gracillimum, n.sp.; a sheath, and also there is no chloro$a, b$, young forms ( $\times 330$ ); $c$, phyll in the cell-contents. The mature cell dehiscing $(\times 400)$; species is not uncommon, and small $d$, tip of another ripe speci- forms may sometimes be met with men $(\times 500)$; $c$, var. falciforme, n. var. $(\times 330)$.

## Chytridium clavum, n.sp.

Fig. 3.
Chytridium clavum, n.sp.; $(\times 665)$.

Cellulæ claviformes, apice inflatæ, capitatæ; inferne lateribus ad basin acutam sensim sensimque convergentibus, stipite nullo nec pede. Cytoplasma hyalinum homogeneum.

Cell. long. 20; lat. 2, ap. $3 \mu$.
Lismore (254). In quantity on Hyal. dissiliens.

## Genus Trochisia Kütz.

Syn., Acanthococcus Lagerheim. In every form mentioned below, the contents of the cell were hyaline, without a trace of chlorophyll.

Trochisia hirta (Reinsch).
Cell. diam. s.sp. 27-34; sp.long. 4-6 $\mu$. Lismore (225, 236).
Syn., Acanthococcus aciculiferus Lag.; A. hirtus Reinsch, Genus Acanthococcus, p.240, T. xi., f.1, 5, 15. Reinsch gives diam. $15-32 \mu$, cf. Biol. Richm. R., Pl. vii., f.2, and the dimensions on p. 136 .

Var. elliptica Playf.
Cell. long. s.sp. 74-80, lat. s.sp. 38-62; sp.long. 5-12 $\mu$.
Lismore (236, 244). Biol. Richm. R., p.136, Pl, vii., f.l.

## Trochisia hystrix (Reinsch).

Cell. diam. s.sp. 133; sp. long. $16 \mu$.

## Lismore (236).

Reinsch, l.c., p.241, T. xii., f.25. It ought, by rights, I think, to be set down as a variation of Tr. hirta. Trochisia hystrix; segment Noted in the same sample with that of margin; $(\times 665)$. species and var elliptica. Diam, cell. $43-46 \mu$. Long. spin. 4-7 $\mu$. Reinsch

Fig. 5.
Trochisia pachy. derma; ( $\times 1000$ ).

Trochisia pachyderma (Reinsch) Cell. diam. s. membr. 18, rugis membr. $2 \mu$ alt.

## Lismore

Reinsch, l.c., p.240, T. xi., f.8, 9, gives diam. $12-19 \mu$. A good number of his other species would seem to be only forms of T'. pachyderma. Eight cells found together, apparently, in a rotifer-skin
Trochisia Lismorensis, n,sp.
Cellule sphærice setis brevibus bifidis dense vestitr. Cytoplasma hyalinum.

Cell. diam. s. setis 26 ; set. long. $4 \mu$.
Lismore (225).
Two species somewhat like this are Tr. brachiolata (Möb.) Lemm., Nord. Plankt.,

Fig. 6. Flagell., de., p.16, fig.58, and Tr. (Acanth.) Trochisia Lismorenspinosa (Reinsch), l.c., p.241, T. xi., f.6. The sis, n.sp.;( $\times 66$ 5̈). former is a marine species, and, in both, the spines, though bifid,
are of a different character, much stouter and more like elongated verruce. In Tr. Lismorensis, they are mere bifid sete, very fine and thickly strewn.

SCHIZOMYCETES.
Micrococcus prodigiosus (Ehr.) Cohn.
The two zoogloe-forms attributed to Bacterium termo, Biol. Richm. R., p.140, Pl. vii., f.14, belong, probably, to this schizophyte. B. termo has, indeed, a similar zoogloea-state, but coarser in the grain, on account of its larger cells.

Lismore (206).
Bacterium termo (Ehr.) Duj.
$\Rightarrow \quad$ Cell. long. 2-4, lat. $1 \mu$; plerumque $3 \times 1 \mu$. Lismore (185, 225).

Fig. 7.

I have never been able to see the flagella, but, by the way in which the cells tend to adhere to Bacterium termo; the glass-slip by one end for some moments after $(\times 1000)$. the other end is free, I consider they have a flagellum at each end. This getting temporarily stuck to the glass-slip by a flagellum is quite a common occurrence among the smaller flagellates, both animal and vegetable.

Bacterium gigas, n.sp.
Cellulæ bacilliformes ex inflationibus globosis 4-6 contingentibus compositæ; in extremis flagello singulo preditæ.

Cell. long. 8-12, lat. ${ }^{3} \mu$.
Lismore ( 225 ).

Fig. 8.
Bacterium gigas, n.sp.;
$(\times 1000)$.

Bacillus ulna Cohn.
 Cell. alt. 5-20, diam. $2 \mu$. Lismore (259).
In quantity with B. subtilis, broken filaments in pieces up to $60 \mu$ long. The cells generally $20 \mu$ long, dividing into $10 \mu$ and $5 \mu$. The contents homo-Fig.9.-Bacillus ulna Cohn.; geneous, with scattered granules, large and small. The faint blue colouration, which was apparent, is probably caused by an opalescent refrac-
tion from the granules, and not by any colouring matter. $B$. ulna is very rare; I remember to have noted it only once before.

## Spirillum volutans Ehr.

Anfract. diam. 7, alt. 12; fil. diam. $1 \frac{1}{2} \mu$.
Lismore (178, 186, 187, 233).
This is exactly the size of Cohn's broadest figures.
Var. maximum Playf.
Anfract. diam. 14, alt. 24; fil. diam. $1 \frac{1}{2} \mu$.
Lismore (233).
The spirals are twice as broad as in the type, cf. Biol. Richm. R., p.139, Pl. vii., f.8.

## Spirillum laxissimum Playf.

Long. 10; fil. diam. $1 \mu$. Anfractibus singulis.

Lismore (236, 259).
Cf. Biol. Richm R., p.139, Pl.vii., f.10. Spirochcete plicatilis(f.10), and Vibrio serpens were also observed.

Fig. 10.
Spirochete plicatilis Ehr.; $(\times 1000)$.

Fig. 14. ,, ,, var. australica, n,var.

[^0]:    * "Contributions to a Knowledge of the Biology of the Richmond River," These Proceedings, 1914.
    + Six additional forms, four new, are included from the River.

[^1]:    * The numbers, 176 to 261 , correspond to samples preserved in the National Herbarium, Botanic Gardens, Sydney.

[^2]:    * Or rather re-discovery, for I noted it tirst in Sydney, on August Ist 1909.

[^3]:    * The note at the top of p.478-" this really goes under var. repandum. ... . . Its sides are not so sloping as in var. Finmarkioe"-is evidently erroneous. I must have had some other form in mind. Var. angustius is quite close to var. Finmarkice.

[^4]:    *Janet, Le Volvox, p.143, gives the reference: Arthur Meyer, Die Plasmaverbindungen und die Membran von Volvox globator, aureus, und tertius mit Rücksicht auf die Thiereschen Zellen. 1896.
